Introduction

The World Health Organization (WHO) predicts that by 2050, nearly 2.5 billion people will have some degree of hearing loss with approximately 700 million requiring hearing healthcare services (WHO, February 2, 2024). What remains to be determined is the proportion of individuals with hearing loss who will require implantable hearing devices. Clinicians not currently working with implantable devices may be asking themselves why this matters? The idealist would say, because all audiologists should strive to ensure that each client receives the best possible hearing care. This article outlines bone conduction and cochlear implant systems in general. Our goal is to clarify current criteria and device options for clinicians who do not work directly with implantable hearing devices. Please find here a summary of the key messages found in this article:

1. Informally, the referral criteria can be summed up in the following ways. You should refer for a bone conduction device (BCD) consultation if your client has a permanent outer ear, middle ear, or ear canal disease or disorder that prevents them from successfully wearing standard air conduction hearing aids. This could include ear canal atresia, stenosis, chronic infection, or any issue causing a significant air-bone gap.
2. New recommendations suggest that an individual should be referred for a cochlear implant consultation if they have a pure-tone average (PTA) of at least 60 dB and an unaided word recognition score of 60% or worse (known as the “60/60 rule”) in either ear. Individuals may have severe to profound hearing loss, steeply sloping loss, asymmetric hearing loss or single sided deafness (SSD). While not all individuals with these hearing configurations will pursue implantation, the referral to a CI team is appropriate.
3. Lastly, a referral to an implantable hearing device team does not mean an individual must proceed with surgery. Referring to these facilities helps inform patients of the healthcare options available to them and helps determine the best treatment option. Clinician’s working with implantable hearing devices do not want to poach your patients – in fact, they will likely become your partner in hearing healthcare.

Bone Conduction Implants

When conductive or mixed hearing loss is confirmed, patients will first be referred to an ENT specialist to look at potential medical or surgical treatments that may reverse the condition. If the hearing loss persists, one of the roles of the audiologist is to determine if a hearing aid is appropriate or if a bone conduction device (BCD) could prove a better solution.

Indications for Bone Conduction Devices

Traditionally, BCDs were prescribed to patients who presented with an anatomy that could not accommodate conventional hearing aids. Cases included atresia, microtia and other congenital outer or middle ear issues. BCDs are also a great option for patients with chronic middle ear issues (e.g., discharge). Unlike traditional hearing aids, BCDs amplify without occluding the external auditory canal thus minimizing moisture accumulation and decreasing the risk of infections (Backous et al., 2022).

Bone conduction devices are also viable for mixed losses with a significant conductive component. Patients with an air-bone gap greater than 30 dB often perform better with a BCD than a traditional hearing aid (de Wolf MJ et al., 2011).

In a small number of cases, a BCD can also serve as a solution for individuals with single-sided deafness (SSD) who are not suitable candidates for a contralateral routing of signal (CROS) system or cochlear implantation. The device functions similarly to a CROS system, with the key difference being that the sound signal is transmitted to the cochlea of the better-hearing ear via bone conduction. A BCD trial may be offered if a patient is not satisfied with a CROS hearing aid.

Candidacy Criteria

Bone Conduction Devices are indicated for patients with conductive or mixed hearing loss, an air-bone gap of at least 30 dB, and good speech discrimination scores (Sanchez-Perez J, 2023). Pure-tone bone conduction thresholds should not exceed 55 dB HL. However, the healthier the cochlea (i.e., the better the bone conduction thresholds), the better the outcomes will be. Since BCDs bypass the outer and middle ear and stimulate the cochlea directly, outcomes are closely linked to cochlear health. As a patient's bone conduction thresholds worsen (e.g., presbycusis), the benefit from a BCD decreases. In cases of progressive hearing loss, a BCD may not be able to provide adequate gain and clarity may decrease over time. Other alternatives (such as CI) may be considered in these situations.

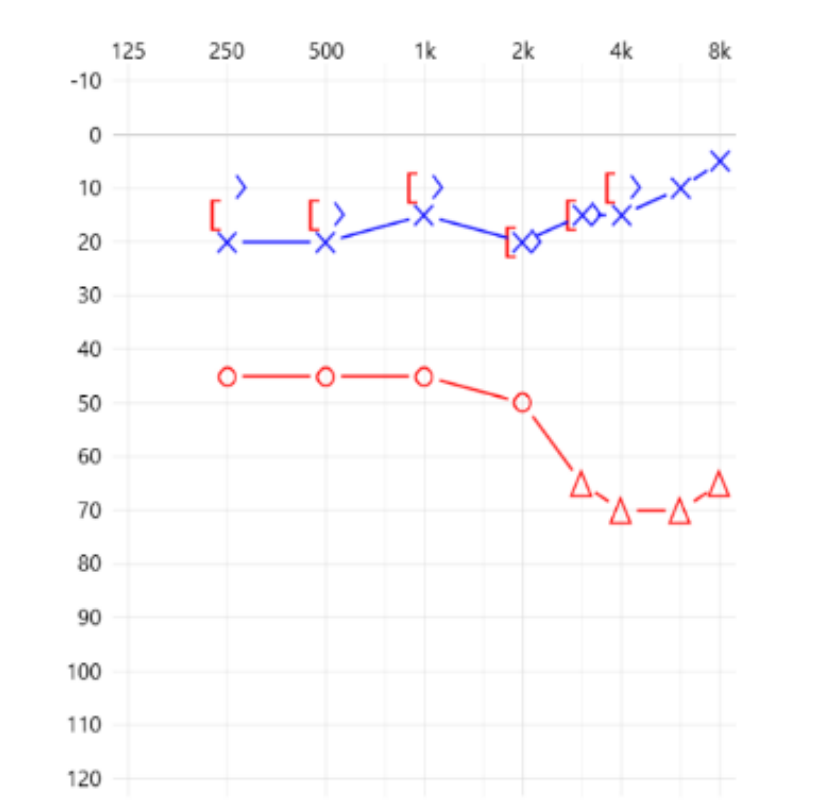

A trial with a BCD fit on a softband or headband is typically conducted for potential candidates. While soft band or headband trials can be done in the clinic patients should trial a device at home to evaluate its effectiveness, benefits, and limitations. A trial at home helps patients develop more realistic expectations and improves BCD acceptance.

Examples of Good BCD Candidates

Example of conductive hearing loss

Example of mixed hearing loss

Assuming these patients have good word discrimination scores, they should be considered candidates for BCD on their right ear as they present with more than a 30 dB air-bone gap and an average BC threshold that fits most manufacturers' specifications.

Types of Bone Conduction Devices

To choose the appropriate BCD for a patient, an audiologist will consider the patient's audiogram, conduct an evaluation of needs, and take their medical health into account. There are two main categories of BCDs: passive and active devices. These categories refer to how the bone conduction vibration stimulation is delivered to the cochlea. Passive or over-skin drive devices transmit vibrations through the skin to the bone. In contrast, active or direct bone drive devices apply vibrations directly to the bone. These are broken down into further sub-categories depending on the processor's attachment.

Passive, Non-Surgical Bone Conduction Devices

Bone Conduction Devices do not always require surgery. Depending on the manufacturer, processors can be secured to the head using several methods, including soft, stretchy headbands, metal or plastic headbands, or adhesive stickers. Clinicians should remember that the functional output of non-surgical BCDs varies with skin and hair thickness.

Passive non-surgical BCDs are often used in the following cases:

1. <5 years of age;
2. for patients with fluctuating conductive hearing loss;
3. patients with insufficient bone density or poor bone quality;

4. and for those who cannot or do not wish to undergo surgery.

Active Percutaneous

Active percutaneous BCDs utilize a surgically implanted, osseointegrated screw with a connected abutment that protrudes through the skin. The abutment is used as the coupling mechanism for the sound processor. Proper care of the abutment is essential in maintaining the integrity of the surrounding tissues. Complications associated with poor care and maintenance have led to percutaneous devices becoming a less popular treatment option. However, percutaneous devices may be preferred when there are concerns regarding the surgical process. Specifically, the abutment placement can be completed in less than one hour and under local anesthetic. Consequently, active percutaneous devices may suit patients who cannot undergo general anesthesia or prefer less invasive surgery (Wojciech, 2022). The fitting range for percutaneous devices is also wider than that of transcutaneous devices meaning individuals with poorer bone lines can still receive treatment.

Passive Transcutaneous

Passive transcutaneous BCDs also utilize a surgically implanted osseointegrated screw but connect to an internal magnet rather than an abutment. The sound processor attaches to an external magnet which is used to transmit sound to the internal magnet and implant. As with non-surgical options, the functional output of passive transcutaneous devices is impacted by skin and hair thickness.

Active Transcutaneous

Active transcutaneous devices consist of a surgically implanted transducer directly vibrating the bone and a magnetically connected external sound processor. Patients typically experience better sound quality with fewer skin complications, making this device the preferred choice for many patients.

When you encounter an individual with a significant air-bone gap struggling to wear or who cannot wear conventional hearing aids, please consider referring them to your local bone conduction device team. Referrals do not need to specify the exact style of BCD to be used as that can be left up to the specialist team (see Appendix I for list of centers across Canada working with bone-conduction implants).

Cochlear Implants

Evidence from the literature suggests penetration rates for cochlear implantation is less than 13% of eligible adults in North America (Sorkin, 2013; Nassiri, 2022) and less than 60% of eligible children in North America (Sorkin & Buchman, 2016). While there are many reasons for this, one contributing factor is a generally low rate of referrals from audiologists to cochlear implant programs. Contemporary indications for referral for a cochlear implant evaluation are provided below.

A useful shorthand for when to refer for cochlear implant assessment is 60/60 referral guideline (Zwolan, 2020). The 60/60 referral guideline suggests that an individual should be referred for cochlear implant evaluation when the pure-tone average is 60 dB HL or worse and unaided

monosyllabic word scores are less than 60% correct. Following this guideline promotes timely access to cochlear implant surgery with the potential for improved hearing outcomes. This is because a significant contributing factor to performance with a cochlear implant is neural health. When cochlear implantation occurs closer in time to when an individual no longer benefits from a hearing aid in the ear being implanted, their neural health is likely to be better.

The cochlear implant candidacy evaluation process is generally consistent across all patient types. After your referral to a cochlear implant centre, the audiologist will do additional testing to confirm auditory function with an appropriately fit hearing aid. They will also review the individual's hearing history, focusing on duration of deafness and consistency of hearing aid use. Additionally, there will be a medical review to assess the anatomy of the inner and middle ears as well as the viability of the cochlear nerve.

Cochlear implant candidacy assessments can be overwhelming for the person undergoing evaluation. Their hopes are often very high, and they may be desperate for any option that helps them to hear. As a clinician working with individuals with bilateral severe-to-profound hearing loss, it is important that you do not think of cochlear implantation as the “last stop” or a “last ditch effort” in the hearing journey. All professionals who have been a part of someone's hearing journey help to shape the perspectives of the individual seeking this line of treatment. As hearing health care advocates, audiologists should promote cochlear implantation through a positive lens for individuals who no longer benefit from hearing aids. You may be wondering how to counsel clients in a supportive way. Here we share one supportive conversation heard during a Cochlear Implant Evaluation as recounted from a client:

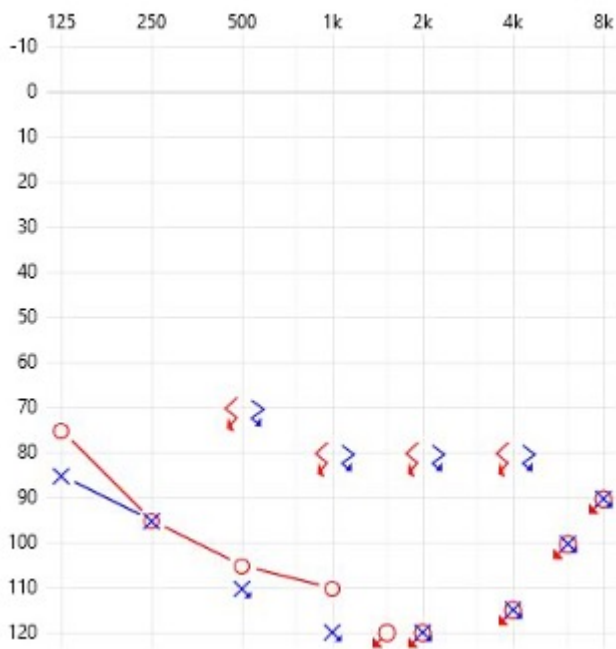

“My hearing aids were not working anymore, and [my Audiologist] said to me: Your hearing loss has progressed in a way that only allows hearing aid(s) to help so much. There are other options that can support your communication and hearing needs. I am not able to help you in the next part of your journey. I would like to connect you with an Audiologist who can guide you through the next steps of your journey. They can help you to better understand how a cochlear implant might help you moving forward.”

Anecdotally, clinics that review their client base for possible cochlear implant referrals are apt to find an increase in revenue by doing so. Clients referred for cochlear implant candidacy often need or choose to proceed with, a new hearing aid purchase instead of, or in addition to, cochlear implantation. With the array of hearing aids and assistive listening devices compatible with implantable devices, referring clinics are also likely to see additional sales even for clients who proceed with implantation.

Traditional Candidacy (Unilateral or Bilateral Cochlear Implantation)

Traditional cochlear implant candidacy is defined by bilateral severe-to-profound sensorineural hearing loss with extremely poor word recognition scores. While traditional candidacy criteria are often well known in the Audiological community, contemporary indications have expanded the number of cases that might benefit from a cochlear implant. Changes to candidacy criteria are driven by successes in individuals who received their implant while being outside the “traditional” criteria. These contemporary indications are often less understood by clinicians working outside of

cochlear implant centres and, depending on your location in Canada may or may not be supported under the provincial or territorial health funding agency.

Asymmetric Hearing Loss/Bimodal Candidacy

Contemporary indications for cochlear implantation stress the importance of assessing each ear individually to provide optimal access to sound in both ears. Thus, if an individual has one ear where the PTA is 60 dB HL or worse and their unaided word recognition scores are below 60%, a referral to a CI centre is indicated.

Example of Audiogram

Example of word recognition scores

RIGHT WRS: 60% at 85 dB HL

LEFT WRS: 0% at 105 dB HL

When access to Cochlear Implantation is timely, and met by the recipient with appropriate motivation and expectations, performance with bimodal hearing can be excellent. Individuals using a hearing aid and cochlear implant together benefit from assistive devices in a new way. These individuals often report improvements in functional hearing in challenging listening environments (e.g., noisy environments, echoic spaces) and when listening over the phone. These hearing benefits require synergies between the team of hearing healthcare providers working with the individual. This creates opportunities for the community-based audiologist to continue working with long-term clients while collaborating with the cochlear implant audiologist.

Electric Acoustic System (EAS) Candidacy

Electric Acoustic Systems (EAS) are for severe “ski-slope” hearing loss patients. In cases where frequency lowering technology is not beneficial (i.e., cannot provide adequate speech clarity) referral to a cochlear implant program for EAS evaluation is appropriate. A combination of new surgical techniques and innovative cochlear implant array design have allowed for the preservation of hearing such that the sound processor can provide both acoustic and electric outputs in some cases. For individuals with severe ski-sloping hearing loss, acoustic output can be used in the good/better hearing low-frequencies while the electric signal can provide access to information above approximately 500 Hz to 1000 Hz, depending on the hearing loss. Functionally, these individuals use a hearing aid and a cochlear implant in the same ear provided individual hearing is preserved post-operatively. Candidacy criteria for EAS are similar to those for asymmetric hearing loss, with greater emphasis placed on very poor word discrimination scores as the trigger for referral.

EXAMPLE OF EAS AUDIOGRAM

EXAMPLE OF EAS SPEECH PERFORMANCE

RIGHT WRS: 36% at 75 dB HL

RIGHT AIDED PERFORMANCE

AzBio (65 dB SPL): 50%

AzBio (65 dB SPL) + 5 dB SNR: 10%

CNC Words: 0%; Ph: 30%

LEFT WRS: 24% at 75 dB HL

LEFT AIDED PERFORMANCE

AzBio (65 dB SPL): 40%

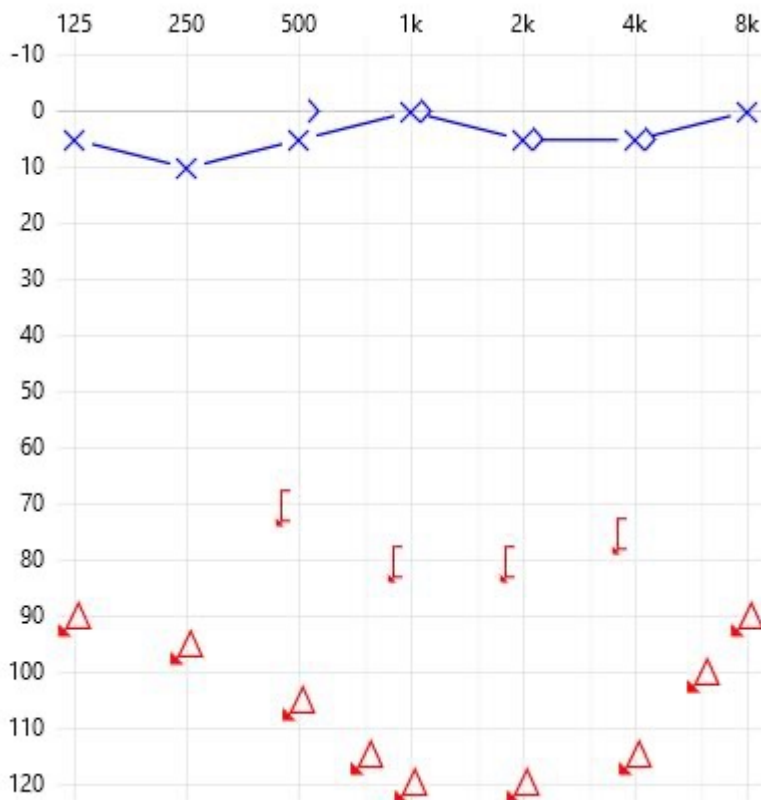

AzBio (65 dB SPL) + 5 dB SNR: 2%

CNC Words: 0%; Ph: 4%

Single-Sided Deafness (SSD) Candidacy

The newest indication for cochlear implant candidacy is single-sided deafness (SSD). Health Canada approved This indication as a treatment option for those with severe-to-profound sensorineural hearing loss in one ear and normal hearing in the contralateral ear in 2020. Indications around the duration of deafness in the ear to be implanted are still being explored, but clinical experience suggests that the shorter the duration of hearing loss is, the better the outcomes will be. Individuals with this configuration of hearing loss may be offered a CROS system or BAHA to see if either option meets their hearing needs. The potential benefits of cochlear implantation for SSD are the ability to restore hearing in the deafened ear itself, to restore a sense of “balance” between the patient’s ears, to improve understanding in noisy environments, to reduce listening effort, and to potentially reduce tinnitus severity.

When presented with a patient struggling with their current hearing technology who you believe may benefit from cochlear implantation, please refer to your local cochlear implant centre. Once again, referral to a cochlear implant team does not guarantee an individual will proceed with surgery. It is simply to allow patients to learn about the options that could potentially improve their hearing function and quality of life (see Appendix II).

Conclusion

Our duty as audiologists is to ensure that every person we see is allowed the best hearing possible. In some cases, our best efforts with conventional technology fall short of the patient’s needs. In cases like those discussed above, we invite you to refer to an implantable hearing technology team. While implantable devices do not “cure” or fully resolve all issues, they may substantially improve an individual’s quality of life. The clinicians you refer to look forward to being your partners in hearing healthcare.
