Figure 1. This illustration depicts a woman experiencing musical hallucinations.

Introduction

Auditory hallucinations, also known as paracusia, occur when the brain perceives sounds without any external source.¹⁻⁴ This condition is complex and often misunderstood, carrying significant implications for an individual's well-being. The experiences associated with these hallucinations can vary widely, ranging from simple sounds—such as clicks or bells—to more elaborate perceptions like voices or music. The emergence of these phantom sounds is driven by intricate brain mechanisms, ultimately influencing individuals' responses.

While these hallucinations are frequently linked to psychotic disorders or substance use, they can also manifest in various contexts, including hearing loss, sensory deprivation, and neurological conditions.³⁻⁶ For instance, patients with vestibular migraines may experience fleeting whispers or musical fragments as their symptoms progress. Similarly, older adults with a long-standing history of hearing loss, without any signs of mental health issues, may hear a familiar tune or melody from their past as if it is coming from their surroundings.

Moreover, it is important to differentiate auditory hallucinations from musical tinnitus—a term that often misrepresents the underlying mechanisms and the nature of the experience. Audiologists, often the first professionals to evaluate patients reporting these complex symptoms, must have a comprehensive understanding of auditory hallucinations, particularly musical ones, for accurate diagnosis and effective management.

Mapping Auditory Hallucinations: Classification Systems and Common Causes

The current literature on auditory hallucinations relevant to audiologists is limited, and no universally accepted classification system exists. In research, auditory hallucinations are generally classified based on the nature and content of the perceived sounds, and divided into two main categories: simple and complex forms.^{2–4} Simple Auditory Hallucinations involve perceiving basic, non-verbal, and unstructured sounds such as clicks, bells, whistling or hissing, which can resemble tinnitus and may be challenging to differentiate from it.^{5,6} The distinction between these symptoms typically relies on identifying the underlying etiology or associated conditions. Complex Auditory Hallucinations involve perceiving intricate sounds such as music and voices. As for simple auditory hallucinations, they can be perceived either unilaterally or bilaterally, and may seem to originate either from inside the head or from the external environment. Let's first look at auditory hallucinations involving the perception of music.⁵

Musical Hallucinations (MH), also called Musical Ear Syndrome, are characterized by the perception of melodies and songs without any external source.^{2,3,5,8–10} Unlike simple auditory hallucinations, MH often presents as well-defined and detailed musical experiences that are often familiar to the individual.^{3,7} These hallucinations can include many sounds, including beloved tunes from childhood like nursery rhymes, folk songs, church hymns, and even commercial jingles. Many patients also report hearing instrumental harmonies, rhythmic patterns, and distorted sounds similar to an out-of-tune radio station. Their duration and intensity can vary, with some individuals experiencing brief episodes, while others report chronic, persistent symptoms that are typically perceived as intrusive and distressing.^{5,11}

MH needs to be distinguished from earworms and musical imagery. Earworms are catchy fragments of songs that involuntarily repeat in the mind but eventually fade, while musical imagery involves the intentional and conscious recall of music. Both phenomena are common and considered part of normal human experience in the general population.^{10–13} Moseley et al., conducted a survey to differentiate these auditory experiences. Their findings indicated that MH are less frequent than earworms and characterized by minimal lyrical content. Additionally, musicians may underreport their MH due to their training and familiarity with musical imagery, making it difficult for them to differentiate between voluntary imagery and involuntary hallucinations.

The most common cause of MH is significant and progressive hearing loss and sensory deprivation, particularly in older adults. However, it has also been documented in younger individuals with conditions such as otosclerosis, where symptoms subsided following successful surgical intervention and improvement in hearing.^{8,14,15} A similar phenomenon occurs in the visual domain, known by vision care professionals as Charles Bonnet syndrome, which involves simple

to complex visual hallucinations in older adults with substantial vision loss.¹⁹ MH can be classified into two main categories:

- **Primary (Idiopathic) MH:** These occur without a specific underlying cause and may be associated with risk factors such as hearing loss, tinnitus, sensory deprivation, advanced age, and social isolation/loneliness.^{4,5,7,8,15,16}
- **Secondary (Symptomatic) MH:** These hallucinations are often linked to identifiable conditions such as traumatic brain injury, stroke, neurological disorders (e.g., vestibular migraines, temporal lobe epilepsy), neurodegenerative conditions, infections, and autoimmune conditions.^{2,3,7,18} Although less common, these hallucinations can also be associated with psychiatric disorders (e.g., schizophrenia, bipolar disorder), sleep disorders, medications affecting the central nervous system, and substance use or withdrawal.^{7,13} Additionally, they may occur due to medical interventions, including cochlear implant surgery and deep brain stimulation.^{5,6,17,20} For a comprehensive overview of these associated causes, please refer to Figure 2.

Type of Musical Hallucinations (MH)	Associated Causes
Primary (Idiopathic) MH	<ul style="list-style-type: none">- Hearing loss- Tinnitus- Advanced age- Sensory deprivation- Social isolation, loneliness
Secondary (Symptomatic) MH	<ul style="list-style-type: none">- Neurological conditions (e.g., stroke, tumors, traumatic brain injuries, focal brain lesions)- Neurological disorders (e.g., vestibular migraines, temporal lobe epilepsy)- Neurodegenerative diseases (e.g., Parkinson’s, fronto-temporal dementia)- Psychiatric disorders (e.g., schizophrenia, bipolar disorder, PTSD)- Sleep disorders (e.g., insomnia, Exploding Head Syndrome, narcolepsy)- Certain medications (e.g., high doses of anticholinergics, antidepressants, antipsychotics, corticosteroids)- Substance use or withdrawal (e.g., amphetamines, cocaine, LSD, psilocybin, MDMA, mescaline)- Medical interventions (e.g., cochlear implant surgery, temporal lobe resection, deep brain stimulation, electroconvulsive therapy)- Infections (e.g., Lyme disease, Listeria)- Autoimmune conditions (e.g., Hashimoto’s encephalopathy)

Figure 2: Musical Hallucinations (MH) and Associated Causes

Auditory Verbal Hallucinations (AVH) are characterized by the perception of spoken words, speech, voices, or conversations without any external source^{1,2,21, 22, 23, 24}. AVH can be both familiar and unfamiliar, with some individuals hearing recognizable voices, such as those of friends or family, while others encounter entirely new voices. The nature and content of these hallucinations

can vary widely, ranging from brief fragments of speech to more elaborate interactions, including voices that converse with, comment on, or command the individual. Like MH, AVH can vary significantly in severity, but are debilitating for most affected individuals.^{21,23}

These hallucinations are most commonly linked to psychiatric disorders, including schizophrenia, bipolar disorder, mood disorders, personality disorders, post-traumatic stress disorder, and sleep disorders.^{1,23,25,26} They can also occur in substance-related conditions, both during use and withdrawal, particularly with hallucinogens (e.g., LSD, psilocybin) and stimulants (e.g., amphetamines, cocaine). Although less frequent, AVH are also reported in neurodegenerative diseases such as advanced-stage Lewy body dementia and Parkinson’s disease-related delirium, where they are often regarded as cornerstone symptoms of the condition.^{16,27,28} For a comprehensive list of associated causes, refer to Figure 3.

Type of Auditory Verbal Hallucinations (AVH)	Associated Causes
Primary (Idiopathic) AVH	<ul style="list-style-type: none">- Social isolation- Loneliness- Severe stress- Lack of sleep- Sensory deprivation, reduced stimulation
Secondary (Symptomatic) AVH	<ul style="list-style-type: none">- Psychiatric disorders (e.g., schizophrenia, bipolar disorder, major depressive disorder with psychotic features, schizoaffective disorder, post-traumatic stress disorder)- Personality disorders (e.g., schizotypal personality disorder, borderline personality disorder)- Sleep disorders (e.g., narcolepsy, insomnia, sleep apnea, hypnagogic and hypnopompic states)- Certain medications (e.g., high doses of antipsychotics, anticholinergics, antidepressants, corticosteroids)- Substance use or withdrawal (e.g., alcohol, amphetamines, cocaine, LSD, psilocybin, MDMA, mescaline)- Neurological conditions such as stroke, tumors, traumatic brain injuries, and focal brain lesions affecting regions like the temporal and frontal lobes, thalamus, hippocampus, and basal ganglia- Neurodegenerative diseases including Lewy body dementia and Parkinson’s disease.

Figure 3: Auditory Verbal Hallucinations (AVH) and Associated Causes

Auditory hallucinations can be understood as existing on a continuum, ranging from everyday perceptual experiences (e.g., earworms, musical imagery) to conditions like tinnitus and more complex clinical issues like MH and AVH.^{10,24} This perspective also highlights that, although tinnitus and MH are commonly linked to hearing loss and AVH to psychiatric conditions, all three can occur in the same patient or in succession. This overlap indicates that these symptoms may exist along a spectrum rather than as distinct categories.^{29,32} Although classifying auditory hallucinations as either psychiatric or non-psychiatric may oversimplify the issue, this distinction

can still help clinicians make appropriate referrals.

Epidemiological Insights: Understanding the Prevalence of Auditory Hallucinations

Auditory hallucinations, including MH and AVH, are more common than often recognized. Epidemiological studies suggest that 10-15% of the general population may experience occasional auditory hallucinations.^{5,30,33} Among these, AVH are significantly more prevalent than MH, especially in psychiatric conditions, with 75% of individuals with schizophrenia and 40% of those with PTSD.^{25,31} It is hypothesized that MH are less reported and documented than AVH due to factors such as limited awareness, unclear definitions, and a predominant focus on AVH in clinical and research settings.³³

A comprehensive observational study by Linszen et al., found that MH and AVH are prevalent among older adults with hearing loss, particularly those with severe deficits. The study revealed that 16.2% of individuals with hearing loss experienced auditory hallucinations in the past four weeks, increasing to 24% in those with severe hearing loss, compared to 5.8% in those without hearing loss. Additionally, 80.6% of those with auditory hallucinations also experienced tinnitus, compared to 70.3% in those without hallucinations. Finally, auditory hallucinations, including both MH and AVH, are reported more frequently by females, with an overall female-to-male ratio of approximately 2:1. The reasons for this gender difference remain unclear.^{4,5}

Comparative Clinical Presentations of MH and Tinnitus

Musical hallucinations (MH) and tinnitus often co-occur and can both be triggered by risk factors such as advanced age, hearing loss, and sensory deprivation. Due to their high prevalence among individuals with MH, some researchers posit a link between tinnitus and the development of these hallucinations. However, both conditions differ significantly in their cognitive and emotional impacts and their implications for diagnosis and treatment. Tinnitus is generally experienced as a persistent, simple, and often unfamiliar internal sound, while MH are characterized by complex, often familiar music or songs perceived as coming from the environment. While 15–20% of individuals with tinnitus report bothersome symptoms that can affect their quality of life, most individuals with MH face distress, fear, and embarrassment, as these hallucinations often challenge their sense of reality.^{3,13,34–36} Due to concerns about stigma, many individuals with MH may feel reluctant to disclose their experiences. As Oliver Sacks insightfully describes in *Musicophilia*:

*Tales of Music and the Brain*³⁷:

“People with musical hallucinations will often search for an external source—a radio, a neighbor’s television, or a band in the street—and only when they fail to find any such external source do they realize that the source must be within themselves. They might describe it as a tape recorder, a jukebox, or an iPod in the brain—something autonomous with its own will, not felt to be a controllable, integral part of the self. The existence of such phenomena in one’s head can evoke bewilderment and, not infrequently, fear. There is often concern that one might be going mad, or that the phantom music could signal a serious underlying condition such as a tumor, stroke, or dementia. Such fears often inhibit people from acknowledging their hallucinations; this reluctance may partly explain why MH have long been considered rare, though it is now

understood that this is not the case.”

Neural Mechanisms behind MH: A Complex Symphony of Brain Activity

The exact neural mechanisms underlying MH in older adults with long-standing hearing loss and no psychiatric abnormalities remain poorly understood. However, it is widely recognized that hearing loss and sensory deprivation are significant risk factors, particularly in that population.^{8,38,39} Prolonged hearing loss initiates a cascade of neurophysiological changes that impact both auditory processing and cognitive function.^{40,41} As the brain is exposed to repeated and diminished auditory input, it undergoes maladaptive changes—such as the reorganization of neural pathways and alterations in cortical thickness—that can result in the perception of phantom sounds, including music.^{42,43} In the absence of external sounds, the brain compensates by increasing activity not only in auditory processing areas, such as the superior temporal cortex, but also in regions linked to memory, attention, and emotional regulation, including the hippocampus, amygdala, and prefrontal cortex.¹¹ This overcompensation engages stored musical memories to fill the gap, leading to the generation of “phantom” music.

Although an extensive body of research has examined auditory verbal hallucinations (AVH) associated with psychiatric conditions, there has been comparatively less focus on the neural mechanisms underlying MH in individuals with hearing loss, particularly through neuroimaging techniques.^{9,11,44-48} Studies employing Positron Emission Tomography (PET) and functional Magnetic Resonance Imaging (fMRI) have provided key insights into the brains of those experiencing MH, confirming the specific regions activated during these events. As illustrated in Figure 4, findings indicate increased metabolic activity and enhanced connectivity in areas such as the prefrontal, medial, and superior temporal cortex, which are critical for memory and auditory processing.⁴⁶ Research further reveals an overlap between the brain regions involved in music perception and those activated during MH, suggesting that shared neural pathways may underlie both experiences. In contrast, AVH engage distinct circuits related to speech and language processing, including Broca’s area, Heschl’s gyrus, and Wernicke’s area.^{30,49,50} Studies indicate that, in musically untrained individuals, the brain’s right hemisphere is typically more active during musical processing, in contrast to musicians, who tend to show greater engagement in the left hemisphere.^{48,51,52} This shift suggests that musicians may process music similarly to language, utilizing analytical and syntactical aspects, as both music and speech share cognitive and neural resources.⁵³⁻⁵⁵

Figure 4. Neuroimaging analyses in a case of MH. Adapted from Cavaliere et al., “Fronto-Temporal Circuits in Musical Hallucinations: A PET-MR Case Study,” *Frontiers in Human Neuroscience*, 2018. Licensed under CC BY 4.0. This figure includes PET scans compared to controls, showing brain activation in different views (A–C); structural MRI results highlighting cortical thickness (D), a gliotic spot in the frontal region (E), and the uncinate fascicle reconstruction (F); and functional MRI activation during beep, unknown, and known musical stimuli (G–I).

In addition to hearing loss and sensory deprivation, structural brain lesions can contribute to MH by disrupting normal auditory processing^{5,7,51,56}. Lesions resulting from stroke or traumatic brain injury can cause localized damage in critical brain regions, such as the auditory cortex, hippocampus, and amygdala. This damage affects the brain’s ability to process and interpret auditory information accurately, potentially leading to the generation of phantom music.

In neurodegenerative diseases like Parkinson’s disease, MH can occur, although they are less common than visual or AVH and may present alongside symptoms such as delirium.^{27,28} Parkinson’s disease is characterized by abnormal protein deposits known as Lewy bodies in brain regions related to motor control and cognition, leading to progressive motor dysfunction and cognitive decline, which can impact areas involved in auditory perception and memory. Delirium, an acute and reversible state of severe mental confusion, can occur in individuals with Parkinson’s due to various factors, including medication side effects, infections, or metabolic imbalances. This state can exacerbate sensory processing issues, contributing to the experience of MH.

Finally, neurological disorders such as vestibular migraines and temporal lobe epilepsy (TLE) are also associated with MH.^{57,58} Vestibular migraines involve complex brain function changes that lead to headaches, aura, and sensory disturbances, including transient MH caused by cortical spreading depression, which disrupts normal sensory processing. TLE, characterized by recurrent seizures and auras, often results in MH due to abnormal bouts of electrical activity affecting auditory processing in the temporal lobes.

Guidelines for Effective Assessment and Management of MH

Detailed Case History. Proper diagnosis of MH is based on a comprehensive history-

taking.^{18,37,56,59} This should involve questions about the nature of the hallucinations, including whether they involve voices, melodies, songs, or non-verbal sounds and their origin—whether organic or related to psychiatric conditions. It is also important to inquire about associated symptoms and their progression. Are there early warning signs like an “aura” or postdrome symptoms such as headaches or fatigue as seen in vestibular migraines or TLE? Family history is also critical, especially regarding hearing loss, mental health conditions or dementia. Recent physical health, medications, or emotional status changes should also be explored. Gathering this information will help determine if a referral to a specialist, such as a neurologist, ENT, or psychiatrist, is needed for more precise diagnosis and treatment.

Audiological Evaluation. Given that long-term hearing loss is a major factor in MH, a comprehensive hearing evaluation is essential to determine the extent and impact of the loss. If hearing loss is identified, fitting and recommending hearing aids is a critical first step in managing MH.^{8,18,56,59–61}

Hearing Aid Verification. For patients already using hearing aids, verifying the hearing aid output through real-ear measurements is essential, as sensory deprivation is a known risk and aggravating factor for MH. In many cases, patients with recent onset of MH may have hearing aids set below prescriptive gain targets, such as NAL-NL2. Ensuring optimal amplification can help mitigate the impact of MH. Additionally, patients may not be using their hearing aids as consistently as advised. Therefore, counselling on proper usage is critical to enhancing both hearing outcomes and symptom management.

Informational Counselling. Informational counselling plays a vital role in managing MH. Educating patients to help them understand and normalize their symptoms can effectively reduce stress and anxiety, and provide reassurance.³³ This approach also promotes the development of more effective coping strategies.^{62,63} Given the likely bi-directional relationship between MH-related distress and mental well-being, poor mental health can intensify how patients perceive the severity of MH. Increased stress and feelings of annoyance, shame, and frustration may worsen concerns and distress about the symptoms and treatments. Helping patients understand this two-way relationship could lead to more effective management of their mental health and MH.^{62–64} Regular follow-up appointments are important for monitoring progress and adjusting the management plan as needed. If anxiety or depression persists, referring patients to a cognitive behavioral therapy specialist could be beneficial. Additionally, consulting with primary care physicians to explore medical treatments for managing stress and anxiety can further support patient care.

Sound Therapy. If MH persists despite appropriate hearing aid adjustments, sound therapy, similar to tinnitus management techniques, should be considered. This approach may involve sound enrichment strategies at home or sound therapy programs integrated into hearing aids. In a 2010 study by Yutaka and colleagues, AVH in two patients were significantly reduced within a month of sound therapy combined with medication, with no recurrence observed for 31 and 17 months, respectively.⁶⁵

By addressing the various facets of MH, audiologists can offer more comprehensive care and ensure that patients receive the appropriate treatment and support for their conditions.
