Congenital hearing loss is the most common health condition that we screen for at birth.

Children with hearing loss are at substantial risk for delays across multiple areas,

including language, reading, and

psychosocial development. These delays can result in significant, persistent

educational and vocational gaps. The vast

majority of children with hearing loss are

considered hard of hearing, with auditory

thresholds in the mild to severe range in both ears or mild to profound range

unilaterally. Around 90% of children with hearing loss have hearing parents. For

children who are hard of hearing who are acquiring spoken language, our most common

approach to aural habilitation is through amplification. An accurate picture of how

hearing aids support language development in children who are hard of hearing is

essential to implementing scientifically-based intervention and counseling for

caregivers.

Based on findings from the longitudinal, multi-site study, Outcomes of Children with

Hearing Loss (OCHL), two factors related to hearing aids have a long-term impact on

language outcomes of children who are hard of hearing: the amount of daily hearing aid

use and quality of hearing aid fittings. Over time, these factors shape a child's

cumulative auditory experience. Tomblin et al. followed over 300 children with mild to

severe hearing loss from preschool to elementary grades on an annual basis.¹ All children used spoken English as their primary mode of communication and did not have any additional disabilities. The researchers recorded how often children were wearing their hearing aids at each test visit. Each year, children took part in an extensive battery of vocabulary, grammar, and pragmatic language measures. These scores were combined into a single composite index of language ability. While the average composite score for the children with hearing loss was delayed relative to same-age hearing peers at age 2 years, children who wore hearing aids 10 or more hours per day showed steeper growth in their language skills over four years compared to children who wore hearing aids less than 10 hours per day (Figure 1A). In other words, children who were consistent hearing aid users were able to reduce the language gap between themselves and their peers with typical hearing during the preschool and early elementary years. Importantly, the impact of consistent hearing aid use applies not only to children with moderate or severe hearing loss but also to children with thresholds in the mild range.²⁻⁴

Figure 1. Growth in language skills over 4 years.

Maximizing outcomes for children with hearing loss does not just involve wearing hearing aids 10 or more hours per day. If hearing aids are not fit appropriately, they can essentially act like earplugs and cause further delays in language development. For amplification to be successful, audiologists must consistently use best practices to ensure that hearing aids match prescriptive targets and increase access to the speech spectrum (also known as audibility). These best practices necessitate the use of hearing aid verification techniques, specifically measuring the aided long-term average speech spectrum either directly in the child's ear canal (i.e., in situ probe-microphone real-ear measures) or with a coupler in a test box (i.e., simulated real-ear measures),

incorporating individual real-ear-to-coupler difference to account for the difference between the 2 cc coupler and the volume of the child's ear canal). As described in Tomblin et al¹ the researchers measured children's aided audibility via real ear or simulated real-ear measures at every visit. At 2 years of age, there was no significant difference in language scores for children who had the largest benefit in audibility from their hearing aids compared to children with the least amount of benefit, after controlling for unaided hearing levels. Over time, however, the children with better-aided audibility made greater progress in their language skills. By age 6, the children with the highest level of aided audibility showed a two-thirds of a standard deviation advantage over the children with the lowest level of aided audibility (Figure 1B). The key point is that the cumulative effect of auditory experience helps children develop stronger language skills over time. Stronger language skills have also been shown to have a positive cascading effect on other domains of development, such as speech recognition in noise, early literacy, and theory of mind.⁵⁻⁷

The positive impact of hearing aids on language development persists into middle childhood (i.e., up to age 12 years). In a recently accepted article, Tomblin et al. found that aided audibility moderated the relationship between unaided hearing levels and language outcomes in elementary-age children who are hard of hearing.⁸ For children with higher aided audibility (i.e., access to greater than 70% of the speech spectrum), unaided hearing levels did not have a significant association with language scores. Also, children with moderate hearing loss had language scores in the average to above-average range compared to an age-matched group of children with typical hearing. Taken together, these results indicate that for children with mild or moderate hearing loss, aided hearing via hearing aids diminishes the negative effect of decreased unaided hearing on language outcomes. Furthermore, oral language skills serve as an intervening link between unaided hearing and academic outcomes (i.e., reading, writing, and math) in second and fourth grade.

In conclusion, consistent hearing aid use and well-fit hearing aids support learning to listen and listening to learn for children who are hard of hearing. Audiologists and related service providers should be proactive in recommending amplification for children with hearing loss, including children with mild bilateral hearing loss or unilateral hearing loss, rather than operating on a failure-based model.⁹ Future research

is needed to determine whether cumulative auditory experience continues to support language learning efficiency and language growth rates and reduces the risk of educational and vocational gaps for adolescents and young adults with early-onset hearing loss.
