Hearing and Deafness: Crossmodal Perception and Plasticity

By Marie-Soleil Houde, MScS (A), François Champoux MSc, MScS (A), PhD

At the crossroads of clinical audiology and scientific research lie many important questions on the brain and hearing. It is these questions that fuel research at the Auditory Neuroscience Research Laboratory of the University of Montreal. The laboratory members' various areas of expertise in clinical audiology and cutting-edge neuroscientific research complement one-another as we seek a deeper understanding of multisensory integration and the mechanism underlying cortical auditory plasticity. By combining audiological, electrophysiological, oculometric, optoelectrical, posturographical and imaging research methods, we

can investigate these clinically relevant issues with intensive scientific rigor. Since its inception, the investigations performed in our laboratory have helped expand understanding of the interaction between the auditory system and the other senses in hearing and deaf individuals.

Multisensory Interaction and Plasticity in the Normally Hearing

A decade ago, a member of our research team helped uncover the multisensory role of the inferior colliculus, a subcortical structure then largely considered unisensory.¹ This finding revealed this structure's role in multisensory speech processing for the first time. Following this, we investigated the divergent characteristics of audiovisual speech and non-speech processing through the use of various illusory tasks.^{2,3} We then furthered these investigations on multisensory interactions by looking beyond the domain of audiovisual integration. These investigations continue to this day as we further explore the influence of auditory input on motor and sensory systems.^{4,10}

Crossmodal Perception and Neuroplasticity in the Deaf

Many studies have shown that blindness may lead to functional changes in the remaining intact senses. These researches in the blind have shown that neuroplasticity leads to positive and advantageous outcomes for most of the remaining sensory modalities (e.g., from our research team members and collaborators.^{11,16} Studies in the deaf, however, suggest that crossmodal neuroplastic changes may vary across modalities.¹⁷ Sensory changes seem to lack uniformity in the deaf, contrary to changes seen in the blind, as they vary between the heightening and lowering of abilities.¹⁴ Though fragmentary, these data have revealed the consequences of crossmodal neuroplasticity in the deaf and have highlighted the consequences of faulty adaptation for rehabilitation.¹⁸ This is particularly true in light of rehabilitative efforts following cochlear implantation. For decades, hundreds of studies have explored auditory performance in cochlear implant (CI) users with no interest for the influence other sensory modalities may have had on these results. The general consensus brought forth by these studies stated that auditory performances were practically unpredictable.¹⁹ However, over the past decade an increasing number of researches have shown that crossmodal plasticity appears to be the key factor in limiting hearing and triggering multisensory conflicts for CI users.^{20,28} These findings have led to the understanding that crossmodal perception and plasticity can no longer be ignored in rehabilitation strategies in CI users. As of late, there is a critical need for perception-training programs to be adapted based on the nature and extent of crossmodal changes in CI users.²⁵ Unfortunately, knowledge regarding the mechanisms underlying sensory-motor changes following deafness is still strikingly lacking. Even more troublesome, we know even less of what remains of these alterations after the restoration of the auditory inputs through a CI and of the conflicts that they may generate across the senses. In fact, there is still much debate over the identity of the systems that are altered and the mechanisms that mediate adaptive or maladaptive neuroplastic changes following deafness.¹⁷ Needless to say, the factors that may constrain or promote these changes are less understood in the deaf,^{14,17,18} and have been practically overlooked in CI users.²⁵ In light of these evidences, or lack thereof, it becomes crucial to unravel the consequence of deafness on both unisensory and multisensory processing in CI users.

The study of crossmodal perception and neuroplasticity is an extremely broad field that requires

thorough investigation on multiple levels ranging from neural systems to behaviour.¹⁸ There is a still debate on research concerning the anatomical and structural changes following auditory deafferentation.²⁹ We also know very little regarding functional implications of these neuroplastic changes. Our research aims to rectify this lack of knowledge for the many characteristics of hearing loss in deaf signers and cochlear implant users. With our collaborators, we have intensively investigated these topics at the Auditory Neuroscience Research Laboratory of the University of Montreal, with a particular emphasis on sensory deprived individuals.^{23,24,26,27,28,30,34} We plan to continue and expand on these investigations in the coming years.

The Auditory Neuroscience Research Laboratory of the University of Montreal is currently composed of 5 doctoral students. These students have all demonstrated a high potential for research and are benefactors of some of the most prestigious provincial and federal scholarships (FRQS, CIHR, NSERC). Moreover, their varied backgrounds, which include clinical audiology, neuroscience, and fundamental and clinical neuropsychology, allows for a rich and dynamic mixture of perspectives. The laboratory itself also receives funding from the IRD, CRIR, NSERC, and FRQS.

Examining, Predicting, and Improving Cochlear Implant Proficiency

By Marie-Soleil Houde, MScS (A); Maxime Maheu, MScS (A); Marie Simon, MSc (P)

In recent years, increasing attention has been paid to sensory changes in individuals having undergone sensory deprivation. Amongst these individuals are the deaf, some of who have regained partial hearing through the use of a cochlear implant (CI). The current body of research studying how deafness alters the perception of the external world suggests that a prolonged period of deafness can lead to significant alterations in sensory processing.^{1,2} This can in turn have a dramatic impact on CI proficiency as greater sensory changes prior to cochlear implantation lead to poorer performances with the device.³⁻⁸ Modern deafness rehabilitation methods integrate these findings and have generally been met with success. Indeed, research data have helped predict functional outcomes prior to cochlear implantation on an individual basis, and have allowed more effective patient counselling and expectation management. These data have also improved our understanding of why some people make better use of their CI while others struggle in specific perceptual situations.

Many researchers have studied the impact of auditory experiences on visual perception, yet very few have investigated how auditory deprived individuals experience other sensory or motor modalities.⁹ It has been proposed that several unexplained daily difficulties observed in the deaf could be related to

deficits in these domains (for examples in the tactile and motor domain.¹⁰⁻¹²

One of the areas of research at the Auditory Neuroscience Research Laboratory of the University of Montreal is to examine, predict, and optimize CI performance for everyday use. For this, we use behavioural, oculometric, optoelectronic, posturographic, electrophysiological and neuroimaging techniques. These studies are performed in collaboration with the CI programming team at the Raymond-Dewar Institute and can be segmented along two axes.

The first axis aims at a better understanding of the perceptual, anatomical, and structural changes in deaf individuals. Moreover, we aim at uncovering the impact of these changes following auditory recovery by cochlear implantation. The second axis aims at optimizing CI performance. These studies investigate methods to increase CI performance through optimization of CI processor parameters as well as rehabilitation strategies to help promote beneficial neural plasticity.

These data will not only provide valuable fundamental insight on the effects of deafness on the brain, but will also further our understanding of some difficulties experienced by these individuals. For instance, much of the understanding of speech occurs in a multisensory environment in which sensory-motor and auditory cues are present. We believe that identifying behavioural changes in CI users has direct and significant implications for recognizing the speech-related difficulties experienced in day-to-day life. More specifically, our research will help identify the systems altered by deafness and the mechanisms and factors that mediate adaptive or maladaptive changes in CI users. We believe these data to be essential for predicting the functional outcomes of cochlear implantation. Knowledge stemming from this research will allow more effective patient counselling and expectation management, and enable more individualized post-implant rehabilitation strategies.

Exploring the Vestibular System: From the Laboratory to the Clinic

By Maxime Maheu, MScS (A), Marie-Soleil Houde, MScS (A)

The vestibular system, a sort of sixth sense, is often taken for granted when it functions properly.¹ However, for someone with a vestibular disorder, living without proper input from this sense can be devastating. Despite the growing interest in vestibular research, many questions remain unanswered to this day. This human factor is the driving force for the vestibular research performed at *Auditory Neuroscience Research Laboratory* of the University of Montreal.

One of our main objectives when conducting vestibular research is: “How can this research be easily and effectively translated for clinical application?” To achieve this, we primarily perform scientific investigations using widely available clinical evaluation methods such as the video head impulse test (vHIT) and the vestibular evoked myogenic potential (VEMP).

The vHIT is a recent technique allowing us to assess the function of all six semi-circular canals² and is based on the head impulse technique (HIT). It uses an infrared camera designed to track pupillary movement and a patient-worn gyroscope mounted on goggles in order to compare eye and head velocity.³ This technique is less intrusive than caloric testing and is as reliable as the much more invasive scleral magnetic search coil.⁴

The vestibular evoked myogenic potential (VEMP) is an electrophysiological technique used to assess otolith function and can be evoked using different stimuli such as: sounds, vibrations and electrical stimuli.^{5–7} Two types of VEMP responses are used in clinical and research settings: ocular-VEMP (*oVEMP*) and cervical-VEMP (*cVEMP*).

The *cVEMP* is an inhibitory response measured from the ipsilateral sternocleidomastoid muscle and originates from the saccule. *oVEMP* is an excitatory response of the inferior oblique eye muscle contralateral to the stimulated ear and is thought to originate from the utricle.^{9,10} VEMP responses are proven to be robust indicators of vestibular system integrity and are independent from hearing abilities,^{11,12} which allow us to use these techniques to assess peripheral vestibular function for patients

suffering from hearing loss.

We are currently using these methods in our laboratory to investigate vestibular functions in various populations with sensorineural hearing loss. For instance, between 20% and 70% of children who present sensorineural hearing loss have concomitant vestibular deficit.⁷ We believe vestibular research in the paediatric population with sensorineural hearing loss to be an important area of scientific investigation for its clinical relevance. Moreover, congenital vestibular deficits can impact gross infant motor development.¹⁴ With the widespread adoption of natal auditory screening program, pediatric vestibular research becomes crucial to help with early identification and development of vestibular compensatory strategies to ensure healthy motor development.

On the other end of the spectrum, it is important to assess vestibular function in an aging population. Risks of falls from loss of balance are more prevalent in hearing impaired older adults.¹⁵ This is a research priority not only from an audiology perspective, but also to help alleviate the important financial burden on the global healthcare system associated with falls.¹⁶

Our research team is currently working on projects with rehabilitation centers across the province of Quebec with the focus of helping to increase quality of life of patients suffering from vestibular disorders.

Exploring Brain Mechanisms Modulating Auditory Scene Analysis

By Sara Pagé, MPA, Simon P. Landry, MSc

Brain plasticity is the process by which structural and functional reorganization occurs in the brain in response to physiological and environmental changes.¹ Since deafness or hearing loss can cause compensatory changes at various levels of the central auditory pathway,² audiologists regularly encounter this seemingly fundamental process. Plasticity can also occur for individuals who use hearing aids or cochlear implants since the brain must adjust to the new sensory input and compensate for the effects of auditory deprivation to achieve successful rehabilitation.³ For this reason, it is important for audiologists to be aware of this phenomenon, but also for audiology research to investigate the effects and underlying mechanisms of auditory plasticity to keep providing the best possible clinical care.

The process of brain plasticity is not exclusive to hearing impairments and can also occur in individuals who have undergone auditory training such as musicians. In fact, a better understanding of the processes that can lead to superior auditory abilities could prove to be useful for clinical audiologists. Since clinical intervention often aims at improving auditory perception, this better understanding could lead to novel therapeutic approaches. Many research teams around the world are investigating the benefits of long-term musical training on real-world hearing abilities. One important finding suggests that musicians have the ability to better understand speech-in-noise.⁴⁻⁶ Similar results have been found for older adults where long-term musical training enhanced hearing abilities for musical and non-musical tasks lead to improve speech-in-noise abilities.⁷

Brain plasticity is also responsible for the superior auditory processing typically associated with blindness. In this case, the unused blind visual cortex is recruited by other modalities for non-visual sensory processing.⁸ This type of plasticity gives important insights into the brain's potential. In fact, research suggests that as little as 90 minutes of visual deprivation could improve frequency and

intensity discrimination,⁹ reduces sound localization inaccuracies,¹⁰ and improves perception of concurrent sounds.¹¹ However, the neural substrates underlying these enhancements are currently unknown. Current research at the *Auditory Neuroscience Research Laboratory* of the University of Montreal is aiming to deepen our understanding of this phenomenon so that the auditory benefits of temporary blindness can be transferred to a clinical setting.

Understanding brain plasticity is a fundamental aspect of audiology. Through it, we can better understand auditory pathologies and optimize rehabilitation approaches. The *Auditory Neuroscience Research Laboratory* of the University of Montreal has recently acquired a high-density electroencephalograph to this end. This cutting edge tool combines the superior temporal resolution of electroencephalography with high spatial resolution from numerous electrodes to provide a comprehensive recording of brain activity. With this, we aim to shed light on the processes underlying certain enhanced auditory abilities, namely the ones following musical training and temporary short-term visual deprivation, to benefit clinical audiology.

Multisensory Integration: From Senses to Perception

Simon P. Landry, MSc, Sara Pagé, MPA

Tap a pen on a hard surface. Did you hear a sound? Do you know where the sound came from? Of course you did. For all of your life, without you knowing it, your brain has been associating information from all of your senses in a cohesive percept.¹ This is called multisensory integration and it is the process by which our brain takes the sound of something tapping a hard surface and associates it with the sight of a pen tapping a table. Our brains know that if relevant sounds and sights come from the same area in space, they are likely from the same event.² Without multisensory integration, the world would hardly be more than a cacophony of random sights and sounds!

Everyday processes require multisensory integration. For instance, we typically regard speech as an auditory process, but when you speak with someone in a noisy room you are likely to unconsciously use your vision to complement auditory information.³ Why? Because throughout your life, every time you've seen someone speak, you've heard the words they were speaking. Your brain, through a lifetime of learning, has associated auditory speech with labial movement.

If we learn to integrate senses throughout a lifetime of sensory experiences, then what of people such as cochlear implant users who do not have such experiences? If our interaction with the world is based on the implicit knowledge that a tapping sound is associated with seeing a pen hit a surface, then how does a person who just gained the ability to hear experience the world? This is why multisensory integration, though seemingly extremely fundamental, is essential for a sensory-centered field such as audiology.

For someone who just recently gained the ability to hear, the entire dimension of hearing is independent from everything else. Sound does not have the robust association with vision and touch that it does for most. Watching a dubbed film becomes a challenge. Without auditory experience, all communication comes from vision. Ignoring visual speech information in a dubbed film to focus exclusively on the auditory information becomes a very challenging task.³ Even something as innocuous as shaving requires the integration of sensory information.⁴ How much pressure applied to the skin comes from integrating tactile feedback from holding a razor and auditory information from the blade cutting the whiskers. Does someone who just regained his or her hearing integrate information from touch and hearing in a different way? We have recently investigated this question and found the answer to be informative but also more complex than expected.^{5,6}

Having a deeper awareness of human sensory reality allows us to better understand other people's realities. Though crucial, multisensory integration risks being taken for granted in the auditory rehabilitation process because of its pervasiveness. The fundamental multisensory research performed at the *Auditory Neuroscience Research Laboratory* of the University of Montreal aims at understanding the effects of deafness on the brain, but also its ramifications on individual perception and daily life. Through our laboratory's seemingly fundamental investigations, we can gain great understanding on the way others experience the world.
